We wish to express our appreciation to the entire staff of the High Voltage Laboratory for their unfailing cooperation throughout this project. Needless to say, this thesis would hardly have been possible without their cooperation.

In particular, we are very grateful for the aid of Professor Buechner, who suggested the problem and provided continual supervision and direction during the entire project. His vast experience was invaluable in the solution of many of the particular questions that arose in the course of the over-all problem.

In addition, Dr. Charles K. Bockelman, Dr. Cornelius P. Browne, and Mr. Anthony Sperduto were extremely cooperative and helpful in aiding us in the use of the machine and endoctrinating us into the laboratory procedures.

We should also like to thank Mrs. Mary E. White for her excellent preparation of the manuscript.

# A C K N O W L E D G M E N T S

We wish to express our appreciation to the entire staff of the Ralph Voliaga Laboratory for their excellent cooperation throughout this project. Needless to say, this study would certainly never have been possible without their cooperation.

In particular, we have very greatly benefited from the aid of Theodore Bierhoven, who suggested our problem and provided qualified cooperation and discussion during the entire project. His great experience was invaluable in the solution of many of the psychologic questions that arose in the course of the overall problem.

In addition, Dr. Dorothy T. Bierhoven, Mr. Raymond F. Hyman, and Mr. Anthony Tarantola were extremely cooperative and helpful in adding us to his use of the machine and technologically we thank the Laboratory personnel.

We should also like to thank Mr. Carl T. Hahn for his technical cooperation of the laboratory.

## A B S T R A C T

For about a year, the MIT-ONR Van de Graaff generator has been in operation. It is capable of accelerating charged particles to energies of about 8.5 Mev and of supplying beam currents of about 0.3 Microampere. The generator accelerates the particles vertically downward into a deflecting magnet which acts as a momentum filter and deflects the beam particles through 90 degrees. The particle beam then travels horizontally through a collimating slit system to impinge upon a thin target. The energy spectrum of the product particles emerging at 90 degrees to the incident beam is analyzed by means of an annular magnetic spectrograph which employs 180-degree focusing. The particles are detected by observing the tracks made on nuclear emulsions. The tracks are counted under a microscope; the number of particles is plotted versus diameter of curvature; and from these plots, the energies of the particle groups are computed. The energy of the incident particles is determined by measuring their deflection after they have been elastically scattered from a known target nucleus.

The above equipment was used to investigate energy levels in $V^{52}$ by the $V^{51}(d,p)V^{52}$ reaction. The energy-level system of $V^{52}$ had previously been investigated, mainly by Bartholomew and Kinsey[2] by means of the $V^{51}(n,\gamma)V^{52}$ reaction. Earlier, (d,p) reactions were reported by Davidson[5], Harvey[8], and Abramov[1].

The targets employed in this survey were made by evaporating thin layers of pure vanadium onto Formvar backings. Special hardware and techniques were developed for the target-preparation process which should be of value in evaporating other high-melting point or scarce materials.

The energy spectrum of the product protons was analyzed and proton particle groups corresponding to the ground state and nineteen excited levels in $V^{52}$ were found in the range of excitation energies from zero to about 3.3 Mev. Of these levels, eight were previously unreported.

## A B S T R A C T

For about a year, the Michigan Van de Graaff generator has been in operation. It is capable of accelerating charged particles to energies of about 5.5 Mev and of producing beam currents of about 0.5 Microampere. The generator accelerates the particles vertically downward into a deflecting magnet which acts as a momentum filter and deflects the beam particles through 90 degrees. The particle beam then enters horizontally through a collimating slit system to impinge upon a thin target. The energy spectrum of the product particles emerging at 90 degrees to the incident beam is analyzed by means of an annular magnetic spectrometer which focuses 180-degree rotation. The particles are detected by observing the tracks made on nuclear emulsions. The tracks are counted using a microscope; the number of particles in photon groups, character of curvature, and from these plots, the energies of the particle groups are computed. The energy of the incident particles is determined by measuring their deflection after they have been elastically scattered from a thin, target medium.

The above equipment was used to investigate energy levels in $V^{52}$ by the $V^{51}(d,p)V^{52}$ reaction. The energy-level scheme of $V^{52}$ had previously been investigated, mainly by Burchinow and Slawny[2] by means of the $V^{51}(n,\gamma)V^{52}$ reaction. Earlier, (d,p) reactions were reported by Davidson[1], Sherr[3], and Almqvist[4].

The targets employed in this survey were made by evaporating thin layers of pure vanadium onto Formvar backings. Special backings and mountings were developed for the target-evaporation process which should be of value in evaporating other high-melting point or coarse materials.

The energy spectrum of the product protons was analyzed and proton curvature groups corresponding to the ground state and three been excited levels in $V^{52}$ were found in the range of excitation energies from zero to about 3.3 Mev. Of these levels, eight were previously unreported.

# I. INTRODUCTION

At the present time, a large continuing problem in the field of nuclear physics is the accurate determination of nuclear energy levels. To date, no theory can correlate these levels. Therefore, in general, the collection of accurate nuclear data is continued in the hope that the data will point the way to an adequate theory of nuclear forces.

For several years, the M. I. T. air-insulated Van de Graaff generator with its annular magnetic spectrograph for particles emerging at 90 degrees to the incident beam provided a most productive method of accurate energy-level determination. The spectrograph provided a means of analyzing the energy of the product particle groups to an accuracy of 0.1 percent. The energy of the bombarding particles was well-defined and regulated so that thin targets would yield clearly defined emergent particle energy groups.

However, a major limitation of this air-insulated generator was the maximum beam energy available; about 2 Mev. This low energy limited the field of investigation to fairly light nuclei.

Within the past year the MIT-ONR generator has been placed in operation and has operated at energies in excess of 8 Mev. Professor Buechner encouraged us to make a preliminary investigation of medium- to high-atomic-numbered elements to determine what special problems might be encountered in this untried region. Since

## 1. INTRODUCTION

In the present time, a large quantitative question in the field of nuclear physics is the accurate determination of nuclear energy levels. To date, no theory can accurately treat these levels. Therefore, in general, the utilization of accurate nuclear data is restricted to the hope that the data will point the way to an adequate theory of nuclear forces.

For example, Wu et. al. T. 1. T. established that the coulomb penetration with the angular momentum dependence for quadratic energy-loss at 10 Mev/amu in the heaviest ions provided a more precise method of measuring energy-level determination. The experiment provided a means of analyzing the energy of the ground quadratic ground to an accuracy of 0.1 percent. The energy of the neighboring quadratic was well-defined and significant so that this targets would yield clearly defined resonant quadratic energy groups.

However, a major limitation of this sub-threshold resonance was the maximum beam energy available since 3 Mev. This low energy limited the field of investigation to fairly light nuclei.

Since the past year the HP-TC generator has been placed in operation and has operated at voltages in excess of 3 Mev. Therefore further consideration to be made a preliminary investigation of reactions to high-energy-resonance elements in this material region. Since

time was a limitation in our problem, we confined our study to elements which are largely monoisotopic in nature. We succeeded in making workable targets of tantalum, cesium, and vanadium and did a small amount of preliminary work on each. Our conclusions were that satisfactory energy surveys in this region were possible but much more complicated.

For our contribution, we chose to investigate nuclear levels in vanadium using the (d,p) reaction, because it presented various intriguing technical challenges; furthermore, current literature has shown recent interest in this element. Of the several ways that data for a reaction can be collected, we measured the number of emergent protons at 90 degrees to the incident deuteron beam versus emergent proton energy for various fixed deuteron input energies. With these data, we calculated Q-values and energy levels for $V^{52}$ using a standard mathematical technique.

The investigation of levels in $V^{52}$ proved to be most interesting, challenging, and fruitful. In fact, so many proton groups were found that we were forced to interrupt our survey at an excitation energy of about 3.3 Mev in order to analyze and present our data within the time allotted to us.

this was a limitation in our problem, we continued our study to allowance which our largely mechanistic in nature. We succeeded in finding workable values of temperature, motion, and weather and did a small amount of preliminary work on them. The conclusions were that satisfactory energy systems in this region then possible but were more complicated.

For our conclusions, we chose to investigate wind-power levels in southern using the (p,q) measure, because it separates measure intrinsic wind-level dependent information, common differences has chosen remote tailoring to this element. If the reversal says that this for a remedies are to utilized, we recommend the design of energy system as to depend to the conditions between these weather energy using energy for weather time-dependent input energy. With time data, we calculated wind-power and energy levels for using a standard mathematical handbook.

The investigations of levels to $V^{\frac{1}{2}}$ proved to be even extensive, challenging, and fruitful. In fact, we many previous people were found that to were forced to interpret our energy in as weather battery energy of about 1.1 for to order to analyze and measure our data within the time allowed us.

## II. APPARATUS AND EXPERIMENTAL PROCEDURE

### Part A. Equipment

The general procedure followed in the Laboratory in doing a nuclear reaction of this sort is to bombard a target with a deuteron beam of definite energy and to analyze the energy of the protons which emerge at 90 degrees to the incident beam. If the target is sufficiently thin so that the energies of incident deuteron and emerging protons are not greatly "straggled" in passing through the target material, the emerging particles are found to occur in groups of definite energies. These groups correspond to definite levels of excitation in the residual nucleus.

The major equipment used in this problem was the MIT-ONR Van de Graaff generator, a deflecting magnet, a collimating slit system, and the annular magnetic spectrograph. Figure 1 shows the general layout of equipment in the target room.

MIT-ONR Generator. The principles of operation of the Van de Graaff generator are well known. The outstanding characteristics of this accelerator are that it is able to deliver a particle beam of about 4.0- to 8.5-Mev energy and about 0.3-microampere intensity. Figure 2 shows a cutaway of the generator.

Deflecting Magnet. The deflecting magnet (see Figure 1) serves as a momentum filter for the bombarding particles. The

## IV. APPARATUS AND EXPERIMENTAL PROCEDURE

Part A. Equipment

The general investigation followed in the laboratory is dictated by another research of this work is to construct a chamber with a minimum level of detectable energy and to analyze the energy of the protons which emerge at 90 degrees to the incident beam. If the energy is sufficiently high so that the energies of inelastic deuterons and scattering protons can not greatly "shower" in passing through the barrier material, the energetic particles can thereby be made to produce of detectable energies. Some process experienced in detailed levels of specialization in the residual nucleus.

The major equipment used in this problem was the 18-inch Van de Graaff generator, a multichannel analyzer, a multiplier phototube, and the associated electronic equipment. Figure 2 shows the general layout of equipment in the scattering room.

Pulsing Generator. The calibration of instruments of the Van de Graaff generator are well known. The calibration circuit-pulsing of this analyzer are that it is used to deliver a predetermined amount of charge low-to 0.1-kev energy and about 0.2-microsecond duration. Figure 3 shows a schematic of the generator.

Detector Mount. The detector mount (see Figure 3) serves as a convenient fixture for the scattering particles. The

generator accelerates the particles vertically downward into the deflecting magnet where they are deflected through 90 degrees (when the generator is at the proper voltage) into the slit system. Of course, the mass of the bombarding particle is known so that the momentum filter acts as an energy filter. Thus, the deflecting magnet in conjunction with the slit system serves to define the energy of the beam current.

Slit System. The particle beam after passing through the deflecting magnet, travels about 5 feet horizontally where it passes through an energy-control slit set at about 1 millimeter. It then enters a rectangular slot cut in the first pole piece of the spectrograph where it passes an energy-defining slit, which is a horizontal slit about 1/2 mm wide. The beam then passes through the target located in the pole face gap. The purpose of the slit system is to define the beam, limit its energy spread, and supply a corona-control signal for generator voltage control.

Spectrograph. The spectrograph, see Figures 3 and 4, which has been described in detail by Strait[10], provides a uniform magnetic field whose lines of flux are parallel to the incident beam and extend over an annular region of mean diameter 70 centimeters and about 5 centimeters in width.

generator accelerates the particles vertically downward into the deflecting region where they are deflected through 90 degrees (thus the generator is at the proper voltage) into the slit system. Of course, the mass of the deflecting plate is large so that the momentum filter acts as an energy filter. Thus, the deflecting magnet in conjunction with the slit system serves to define the energy of the beam exactly.

Slit System. The particle beam after passing through the deflecting magnet, travels about 6 feet horizontally where it passes through an energy-control slit set at about 1 millimeter. In this sphere a metalographic slit out in the first pole piece of the spectrograph where it passes an energy-defining slit, which is a horizontal slit about 1/2 mm wide. The beam then passes through the target located in the pole face gap. The purpose of the slit system is to define the beam, limit the energy spread, and supply a coarse-control signal for generator voltage control.

Instrumentation. The instrumentation, see Figures 3 and 4, which has been described in detail by Smith[10], provides a uniform magnetic field whose lines of flux are parallel to the trajectory beam and extend over an angular region of even diameter 30 centimeters and about 6 centimeters in width.

Figure 3. A view of the spectrograph, deflecting magnet, and collimating tube.

Figure 3. A view of the scanhorn, deflecting magnet, and collimating tube.

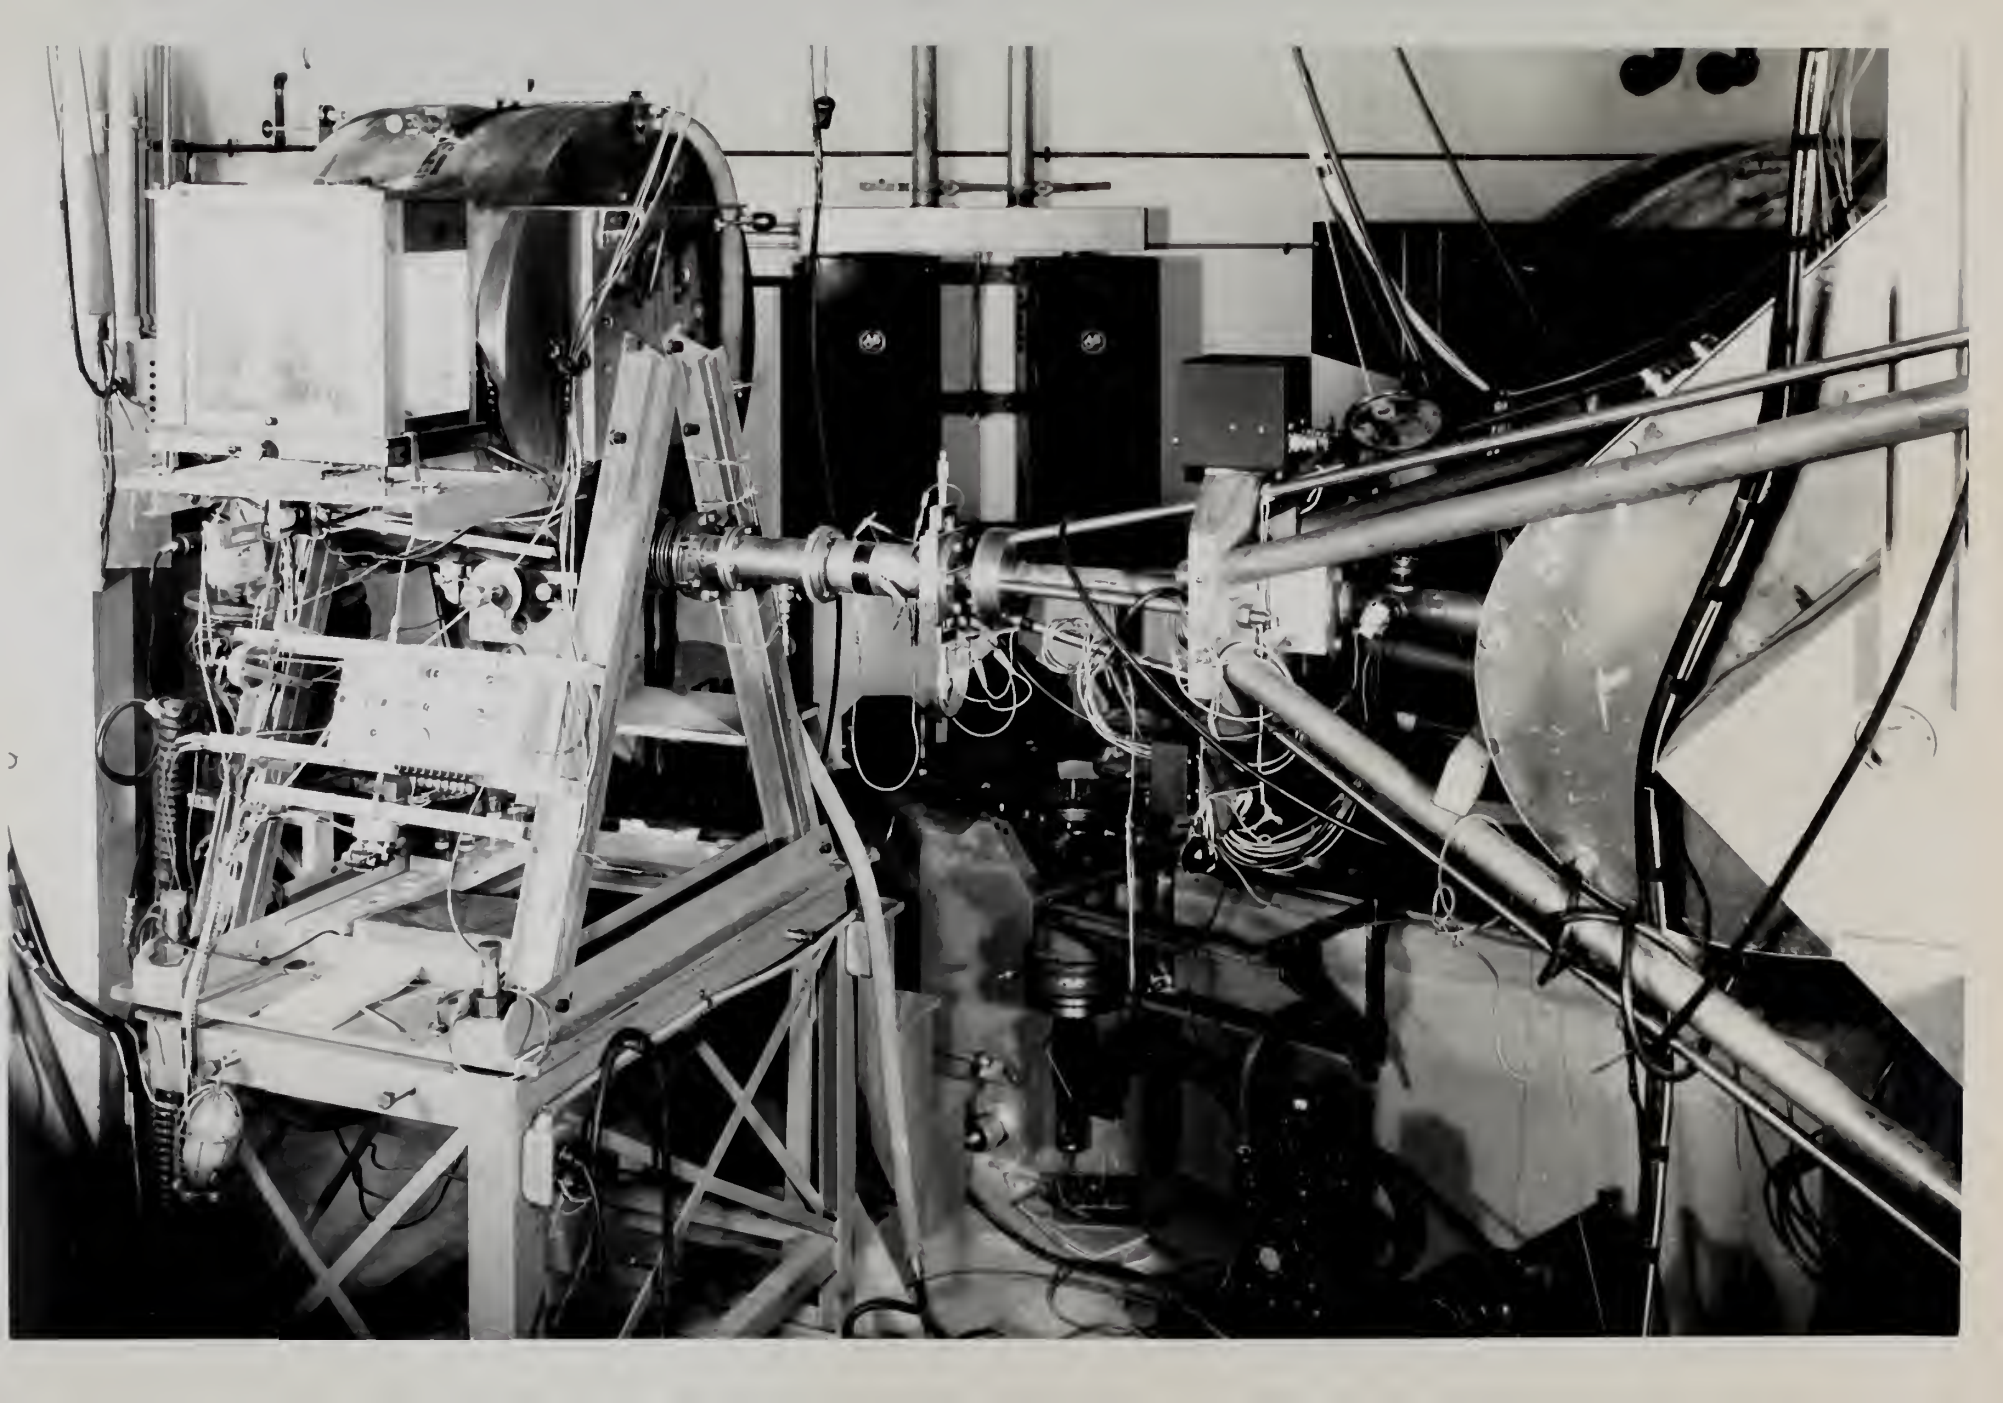

Figure 4. A close-up of the spectrograph where the target chamber at the bottom and the camera box at the top are visible.

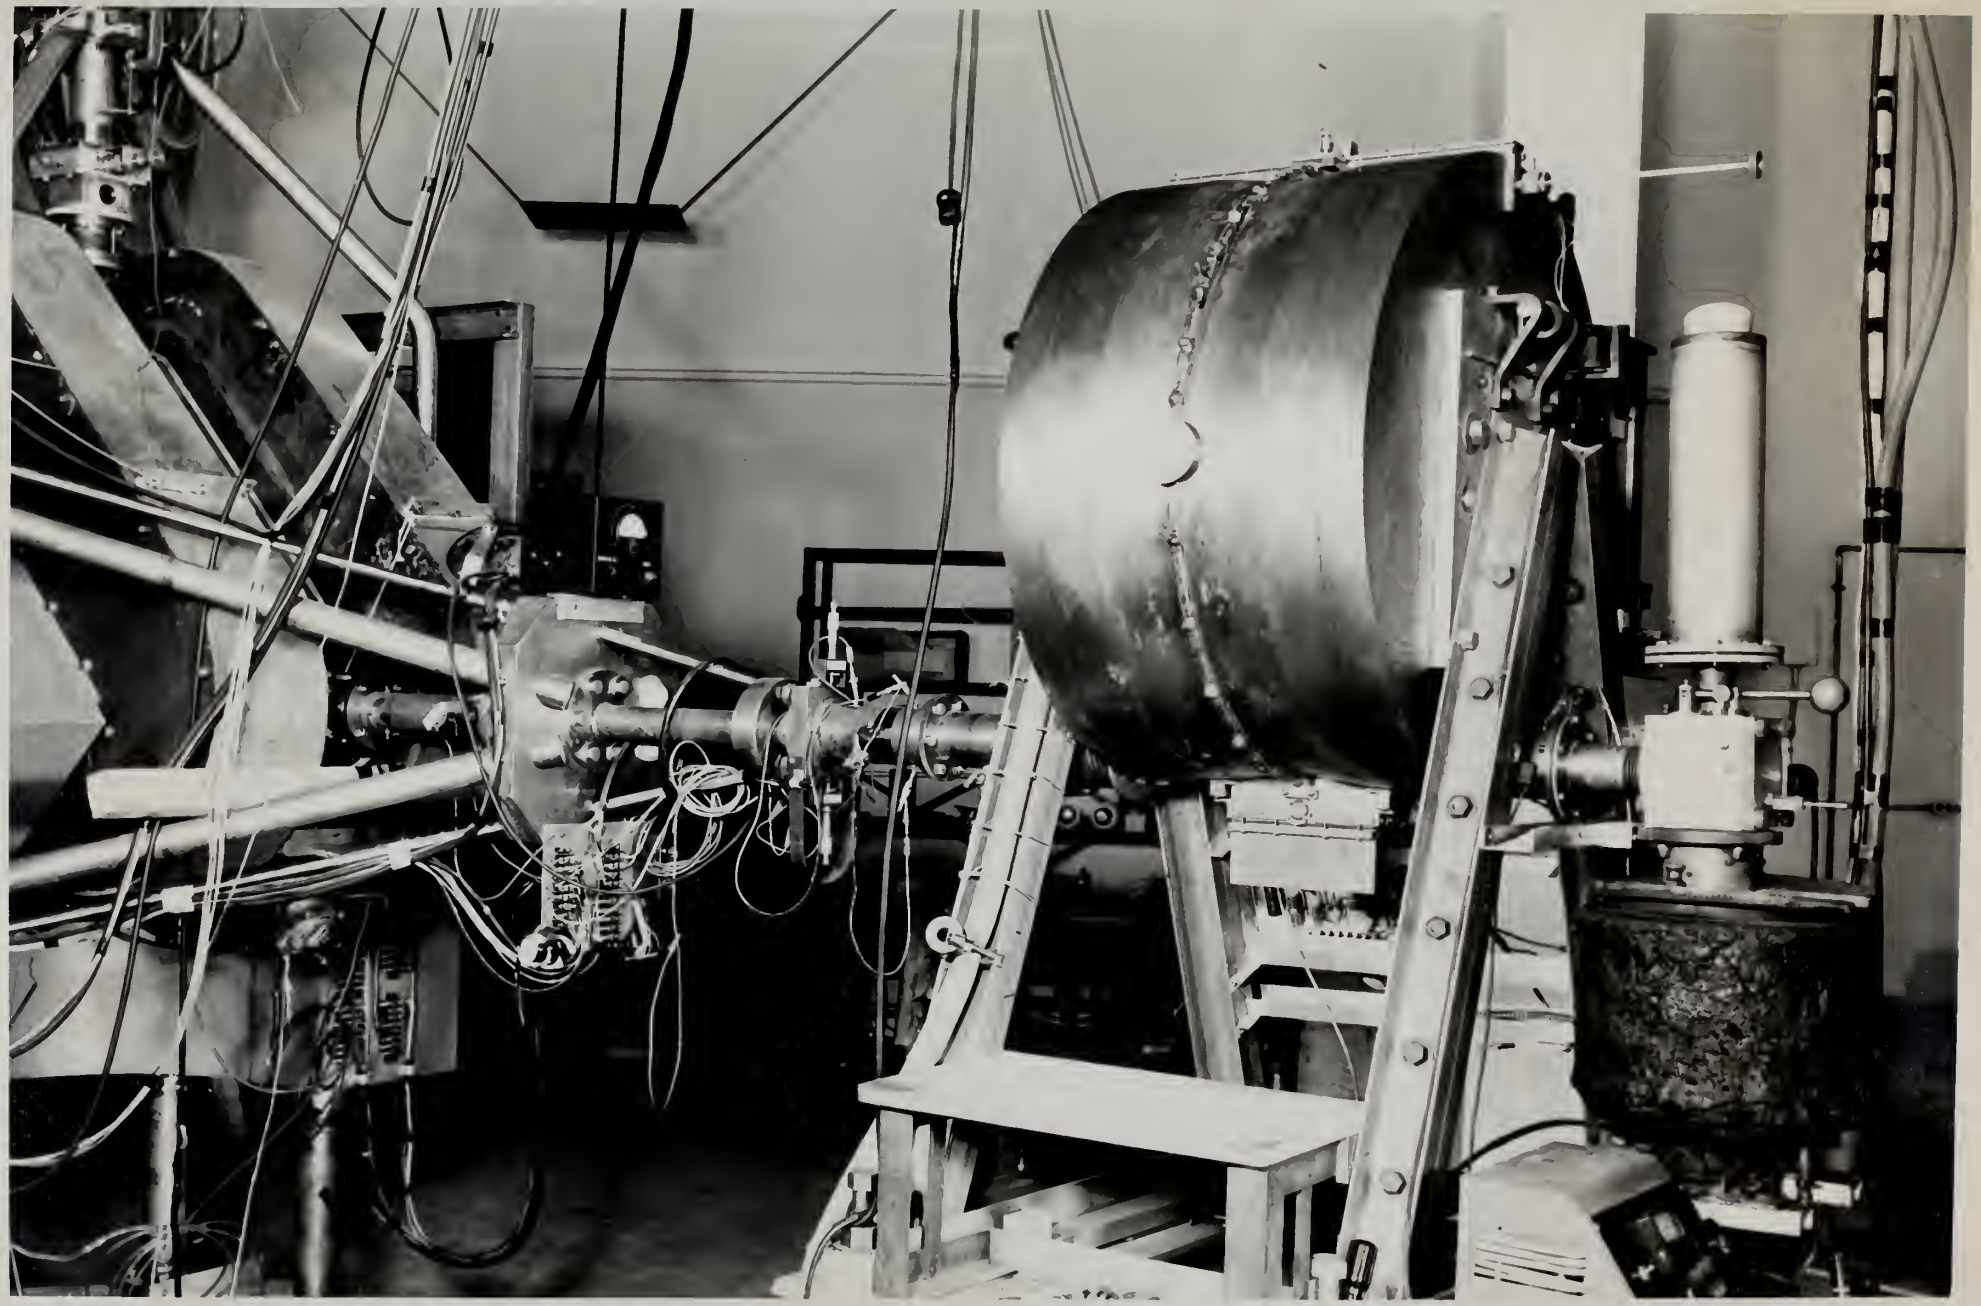


Appended to the spectrograph at the bottom is the target box which houses a rotable wheel, on which seven targets may be mounted radially. Thus, seven targets are available for use without breaking vacuum. The target is so placed that its normal lies about halfway between the direction of the incident beam and that of the charged particle emerging at 90 degrees.

Diametrically opposite to the slot cut to admit the incident beam and target holder, a second slot cut in the pole pieces permits the insertion of the photographic plates used in detecting the charged reaction products. The plates are placed in the field so that the length lies vertically along the diameter of the magnet. Thus, a plate covers a momentum region corresponding to the product of the field and one-half of the effective length of the plate. The Hr covered by a plate is variable depending upon the region; at Hr of about 450 kilogauss-centimeters, the plates covered about 20 kilogauss centimeters. The plates are positioned at about 30 degrees to the plane of the pole pieces. A plateholder, which holds five plates, slides in the camera box and allows for successive exposure of these plates without breaking vacuum.

In conjunction with the camera box is a light and slit system which can cause a sharply defined light beam to shine against the back of the photographic plate when the plate is in the exposure position. This index marks the exact position of the plate in the magnet. Therefore, the distance of a particle group from the

Located in the gamma-ray at the bottom is the target box which houses a vacuum chamber, on which cesium iodide may be deposited evaporatively. Thus, seven targets are available for use without breaking vacuum. The target is so placed that the normal line always halfway between the direction of the incident beam and that of the charged particle emerging at 90 degrees.

Diametrically opposite to the slit and to which the incident beam and target holder, a second slit and in the pair planes permits the insertion of the photographic plates used in determining the charged reaction products. The plates are placed in the field so that the length lies vertically along the diameter of the magnet. Thus, a plate covers a momentum region corresponding to the product of the field and one-half of the effective length of the plate. The far covered by a plate is variable depending upon the region; at 5r of about 1/2 milligauss-centimeters, the plates covered about 20 kilo-gauss centimeters. The plates are positioned at about 30 degrees to the plane of the main phase. A plate-holder, which holds five plates, slides in the camera box and allows for successive exposure of these plates without breaking vacuum.

In continuation with the camera box is a light and slit system which can cause a sharply defined light beam to shine against the back of the photographic plate when the plate is in the exposure position. This index marks the exact position of the plate in the magnet. Therefore, the distance of a particle given from the

index mark is the amount the diameter of curvature of the group is reduced from the calibrated diameter to the index mark.

Connecting the target chamber with the camera box is the "C" chamber which is a 180-degree annular vacuum box, rectangular in cross section, that is slipped between the pole faces of the magnet. It is through this chamber that the product particles travel from the target to the photographic plates.

The target exposure is measured by an integrating circuit developed by Enge[7]. Most of the particle beam continues through the target, through a rectangular slot in the second pole piece to be collected in a biased Faraday cage, and then integrated.

Auxiliary Equipment and Calibration. The photographic plates were Eastman Kodak NTA emulsions of 60-micron thickness. They were counted by means of a Spencer dark-field, binocular microscope, in which 12X eyepieces were used. The objective lens was 20X or 43X. With 20X objective, the field of view on the photographic plate was one-half millimeter by one-half millimeter. For a given setting along the length of the plate, counts were taken across the readable width of the plate.

The separation of the beam line on the target from the index mark on the photographic plate is measured by means of a polonium alpha-standard. A polonium-coated wire is placed approximately in the target position. The field is set and a plate exposed. A

have work in the window the character of variation of the image is modified from the additional disorder to the image work.

Concerning the target detector with the camera for it use for detector which is a 180-degree circular mirror lens, rectangular in cross section, lies in alignment between the main focus of the camera. It is thought that dimmer that the primary particles travel from the target to the photomultiplier plates.

The target apparatus is measured by an integrating circuit developed by Cage[7]. Most of the particle beam continues through the target, through a rectangular slot in the mirror and will often be collected in a closed Faraday cage, and then integrated.

Auxiliary Equipment and Calibration. The photomultiplier plates were Dumont Type 6291 emulations of 60-mirror tubes. They were coupled by means of a Dumont dark-field, binocular microscope, in which 25X eyepieces were used. The objective lens was 20X or 12X. With 20X objective, the field of view on the photomultiplier plate was one-half millimeter by one-half millimeter. For a given exposure along the length of the plate, events were taken across the mid-dle width of the plate.

The measurement of the beam line on the target from the image mark on the photomultiplier plate is measured by means of a polaroid slide-standard. A polaroid-coated wire is placed approximately in the target position. The field is set and a plate exposed. A

microscopic measurement of the separation of the beam line from the polonium wire is made by successively positioning a bombarded target and then the polonium wire in the field of the microscope. The separation of the alpha-group from the index, the field setting, and the separation between the wire and the beam position give a measure of the diameter from beam to index.

The magnetic field is adjusted and measured by the nuclear magnetic-moment resonance method. This method consists essentially of measuring the frequency at which quantum jumps of the orientation of the magnetic moments of $Li^7$ or a proton occur in an aqueous solution of LiCl. The LiCl is contained in a small glass capsule positioned in the center of the pole face gap. A secondary standard is used for frequency measurement. It is "zero beat" daily against one of the broadcast frequency standards of Bureau of Standards station WWV.

Part B. Experimental Procedure

The experimental procedure which was followed was roughly and briefly as follows.

The energy of the bombarding deuterons was established by setting up the desired magnetic field in the deflecting magnet.

The exact energy of the deuterons was measured precisely by exposing a photographic plate to observe elastically scattered deuterons from known target nuclei. (For $E_d$ = 5.00 Mev, and

electronic measurements of the magnetization of the rotor iron from the relaxing rotor is made by measuratory switching a tuned burgess and then the relaxation is the field of the gyromagnet. The measurement of the alpha-spread from the tuned, the field matching, and the measurement between the rotor and the tuned switching a stopper of the flywheel from being in motion.

The magnetic field is adjusted and measured by the motion magnetic-moment resonance method. This method exploits asymmetrically measuring the frequency at which quantum jumps of the orientation of the magnetic moments of $Ia^{7}$ or a proton rotor in an aqueous solution of $LiCl$. The $LiCl$ is contained in a small glass ampoule positioned in the center of the polar face gap. A secondary stand-and is used for frequency measurement. It is "tuned" solely against one of the hydrogen frequency standards of Bureau of Standards solution.

Part 5. Experimental Procedure

The experimental procedure which was followed was crucially and formally as follows.

The energy of the balancing deviceon was calculated by setting up the desired magnetic field in the differentiating magnet.

The exact energy of the deviceon was measured crucially by exciting a photoresistor plate to observe classically measured deviceon from known theory model. (For $B_0$ = 5.00 kOe, and

$E_d$ = 5.74 Mev, $V^{51}$ was used for this measurement; for $E_d$ = 6.48 Mev $O^{12}$ was used.)

After the elastic plate had been taken, successive survey plates were exposed; the deflecting magnet setting was left undisturbed, and adjustments were made only to the spectrograph magnetic field between runs.

The plates were developed and read, and the data were plotted. The experience of the Laboratory[3] has shown that the best ordinate for energy determination corresponds to a point 1/3 of the way up on the high-energy side of a peak. This ordinate seems to remain constant, regardless of target thickness or target exposure.

The calculations were then made, as discussed in Part III.

The bombarding energy was chosen subject to several governing factors. A good approximation for barrier height is

$$B = \frac{Z}{A^{1/3}} .$$

This shows that the Coulomb barrier is about 6.2 Mev for vanadium, so that it was desirable to have an energy of roughly that amount to minimize exposure time. We were limited at the upper end in bombarding energy by the fact that the spectrograph cannot be set up to analyze particles with momentum greater than that corresponding to a value of Hr of 479 kilogauss-centimeters, because the

$E_g$ = 7.35 kev, $\gamma_{32}$ was used for this measurement; for $E_g$ = 6.48 kev $\gamma_{32}$ was used.)

After the atomic plate had been taken, successive energy plates were exposed; the deflecting magnet setting was left unchanged, and adjustments were made only to the spectroscopic apparatus itself between runs.

The plates were developed and read, and the data were plotted. The experiment of the laboratory[5] has shown that the best estimate for energy determination corresponds to a value $\lambda/2$ of the way on the high-energy side of a peak. This estimate seems to remain constant, regardless of target thickness or target composition.

The calculations were then made, as discussed in Part III.

The bombarding energy was chosen subject to several governing factors. A good approximation for barrier height is

$$B = \frac{E}{\lambda/2} .$$

This shows that the Coulomb barrier is about 6.2 mev for uranium, so that it was desirable to have an energy of roughly this amount to minimize exponent bias. We were limited at the upper end in bombarding energy by the fact that the spectrograph cannot be set up to analyze particles with momenta greater than that corresponding to a value of $B\rho$ of 1.72 kilogauss-centimeters. Because the

frequency of the present equipment is limited to 22.1 mcs. This momentum figure limits the energy of the protons to about 10.9 Mev. Since the Q-value of the $V^{51}(d,p)V^{52}$ reaction for the ground state is about 5.08 Mev, the maximum deuteron energy was limited to about 6.5 Mev for the ground state. The minimum effective operating voltage of the generator is about 4 Mev.

Between these two limits, we needed at least two bombarding energies widely enough separated to be of value in establishing the mass of the source of the groups. Thus, we arbitrarily chose to use $E_d$ = 5.00 Mev and $E_d$ = 5.74 Mev for the ground to 1.40-Mev levels and $E_d$ = 5.74 and $E_d$ = 6.48 Mev for the 1.40-Mev to 3.31-Mev levels.

With these bombarding energies, about a third of the proton groups fell in the region of Hr greater than 440, which is a region where the High Voltage group had operated very little previously. Inaccuracies were expected in this area because of slight field fringing at this high field setting. This effect appeared very slight on the basis of our results.

This region of high Hr presented another problem in that, here, both protons and deuterons are energetic enough to penetrate the 60-micron photographic emulsion and, thus, it would be impossible to distinguish protons from deuterons on the basis of track lengths. Therefore, the photographic plates were covered with two

frequency of the present equipment is limited to 24.1 mev. This measurement fixes limits the energy of the neutron to about 12.9 mev. Using the formula of the $\gamma^{63}(\gamma,n)\gamma^{62}$ reaction for the ground state is about 3.68 mev, the maximum electronic energy was limited to about 6.7 mev for the ground state. The minimum effective accelerating voltage of the generator is about 3 mev.

Between these two limits, we needed at least two energetic neutron sources covering so as of value in establishing the shape of the curves of the groups. Thus, we additionally chose to use $E_\gamma$ = 4.00 mev and $E_\gamma$ = 5.75 mev for the ground to 3.10-mev level and $E_\gamma$ = 4.75 and $E_\gamma$ = 6.18 mev for the 1.10-mev to 3.32-mev level.

With these bombarding energies, about a third of the prompt gamma fall in the region of 2 greater than 1.10, which is a region where the high voltage power had operated very little previously. Measurements were conducted in this area because of slight trouble at this high field setting. This effect appeared very slight on the basis of the results.

This region of high $\gamma$ produced another problem in that, here, both neutron and electron are energetic enough to penetrate the 20-inches paraffin shielding and, thus, it was not impossible to distinguish protons from bombarded on the basis of track length. Therefore, the photomagnetic plates were covered with the

layers of 1.5-mil aluminum foil, which was enough to stop deuterons and alpha-particles with this momentum, but it allowed the protons to pass through to the photographic emulsions.

In operating the equipment, our inexperience at first led us into several pitfalls. When any target exposure fails to yield useful information because of an avoidable mistake, the situation is disappointing, to say the least. More important is the fact that several man-hours and machine-hours are wasted. While it would be almost impossible to write completely detailed instructions for the operation of the equipment, the following "do's and don't's" could prove very useful to anyone knowing in general the operating procedure and yet having little operating experience:

1. Do not leave nuclear-track plates in the target room unless they are actually in the spectrograph. The high neutron flux in the room when the machine is operating causes "knock-on" proton tracks in the emulsion at random directions and makes accurate counting difficult or impossible.

2. Position the target so that none of the target frame is visible through the "C" chamber window. The positioning is critical, since the frame can yield a high background if it "sees" both the beam and the "C" chamber. Also, the target yield can be greatly reduced if the beam mark on the target is not well aligned with the "C" chamber entrance.

layers of 1.5-cm diameter foil, which was enough to give darkness and light-particles with this accuracy, but it allowed the protons to pass through to the photographic emulsions.

In operating the equipment, our inexperience at first led to such several difficulties. Even any target arrangements fail to yield useful information because of an available rotation, the orientation is disappointing, by any the laser. Here experience is the fact that several sub-hours and rotation-hours are needed. Still it would be almost impossible to write completely detailed instructions for the operation of this equipment, the following rule's and discussion could prove very useful to anyone looking in general for operating procedure and yet having little operating experience:

1. Do not leave nuclear-track plates in the target from which they are actually in the accelerator. The high neutron flux in the room when the machine is operating causes "fog-out" curves inside in the emulsion as random disruptions and noise accurate counting difficult or impossible.

2. Position the target so that some of the target frame is visible through the TV viewing window. The positioning is critical, since the frame can yield a high background if it "sees" both the laser and the TV monitor. Also, the target yield can be greatly reduced if the laser path on the target is not well aligned with the TV monitor screen.

3. Remember that above an Hr of about 425 kilogauss-centimeters, it is not possible to distinguish between deuterons and protons by track lengths, when using 60-micron film without aluminum foil.

4. If aluminum foil is used, it must be as smooth as possible. Wrinkles tend to broaden the proton peaks and to randomize the angle of particle entrance into the emulsion. If banana oil is used to stick the foil, remember that the surface tension tends to "suck" the oil over the plate, ruining the area it covers. We found that attaching the foil to the plates with scotch-tape tabs was a preferable technique, as well as affording less danger to scratching the delicate emulsion during the foil removal; tabs on one edge act as a hinge after the other edge tabs were severed, thus allowing the foil to be lifted.

5. When loading plates, remember that the camera box can be isolated from the rest of the vacuum system and opened to atmosphere only when the plateholder is in the extreme in or extreme out position and the "C" chamber valve is closed. Opening the camera box to atmosphere at any other time will break the targets by allowing a sudden rush of air to enter the target chamber via the "C" chamber.

3. Remember that above an 18 of vacuum 147 kilovolts-centimetres, it is not possible to distinguish between darkness and vacuum by visual inspection, when using 60-micron film without aluminum foil.

4. If aluminum foil is used, it must be as smooth as possible. Wrinkles tend to broaden the vacuum peaks and to increase the angle of particle emission into the evacuum. If vacuum oil is used to adhere the foil, remember that the surface tension tends to "crack" the oil over the plate, reducing the area it covers. We found that adhering the foil to the plates with scotch-tape also was a profitable technique, as well as attaching lead clamps to accentuate the difficult problem during the foil removal; tape on one edge and at a time after the other edge tape was removed, thus allowing the foil to be lifted.

5. When loading plates, remember that the energy has can be isolated from the rest of the vacuum system and opened to atmosphere only when the photoplate is in the vacuum in or without out position and the "V" chamber valve is closed. Operate the camera box in atmosphere at any other time will break the isolation by allowing a sudden rush of air to enter the large chamber via the "V" chamber.

Part C. Target Preparation

The targets used in this experiment consisted of thin layers of pure vanadium evaporated onto thin Formvar backings which, in turn, were supported on target frames (shown in Figures 5 and 6).

The Formvar backing is prepared by dissolving about 1 gram of Formvar powder in 100 cc of ethylene dichloride. A drop of this solution placed on a smooth surface of distilled water forms a thin film which can be dipped upon the target frame. Film thicknesses of about a thousand Angstrom units can be made in this fasion. We found after considerable experience with the high temperatures developed in the evaporation system that six double layers of the film were the minimum amount which would stand up under the vanadium evaporation. The backings thus prepared are composed of carbon, oxygen, and a trace of nitrogen.

The evaporation system consists of a metal table upon which a bell jar is mounted on an annular rubber gasket. The table houses a liquid-air trap, an ion vacuum gage, a thermocouple vacuum gage, a control panel, a heating circuit, an orifice and plumbing system which leads to a mercury vapor pump, and a mechanical fore pump.

Four bronze rods screw vertically into the top of the table to form the support for the target frames, heating unit, and target material. Two of the rods are "wired" to supply the heat for the evaporation.

Part C. Target Preparation

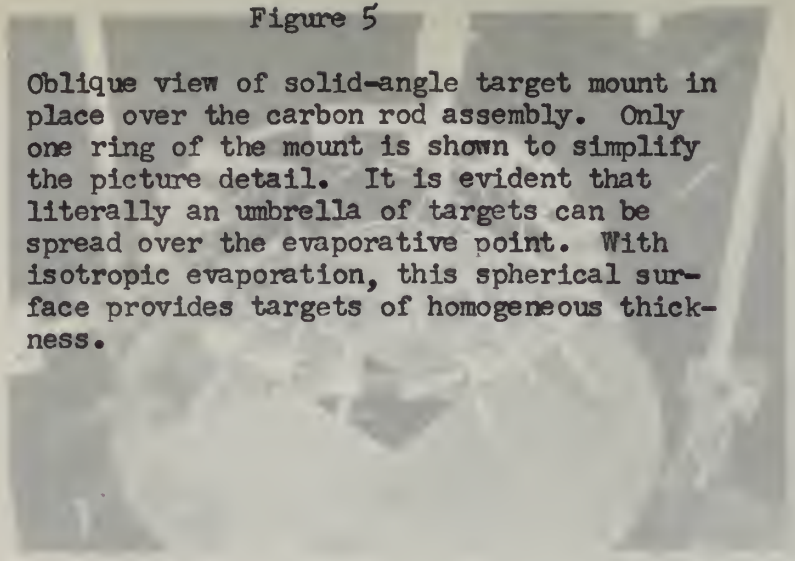
The targets used in this experiment consisted of thin layers of pure metallic evaporated onto thin Formvar backings (film), in turn, were supported on target frames (shown in Figures 2 and 3).

The Formvar backing is prepared by dissolving about 1 gram of Formvar powder in 100 cc of ethylene dichloride. A drop of this solution placed on a smooth surface of distilled water forms a thin film which can be dipped from the target frame. With thicknesses of about a thousand Angstrom units can be made in this fashion. The final other constituents experience with the high temperatures developed in the evaporation system then sets double layers of the film were the bottom layers which would attack to under the evaporation. The backing thus prepared are composed of carbon, oxygen, and a trace of chlorine.

The evaporation system consists of a metal table upon which a bell jar is mounted on an annular rubber gasket. The table houses a liquid-air trap, an ion vacuum gage, a thermocouple vacuum gage, a control panel, a heating element, an orifice and pinching system which leads to a mechanical vacuum pump, and a mechanical flow pump.

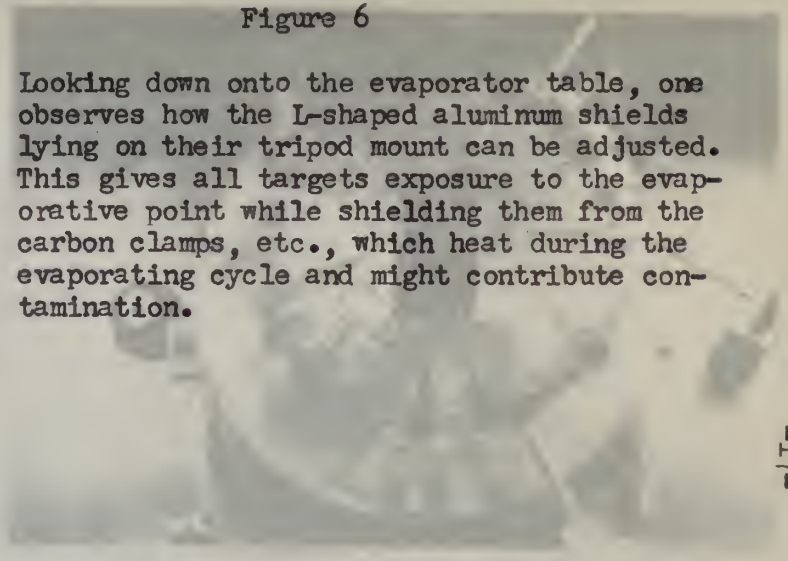
Four brass rods screw vertically into the top of the table to form the support for the target frame, heating coil, and target material. Two of the rods are "hinged" to permit the boat for the evaporation.

Figure 5



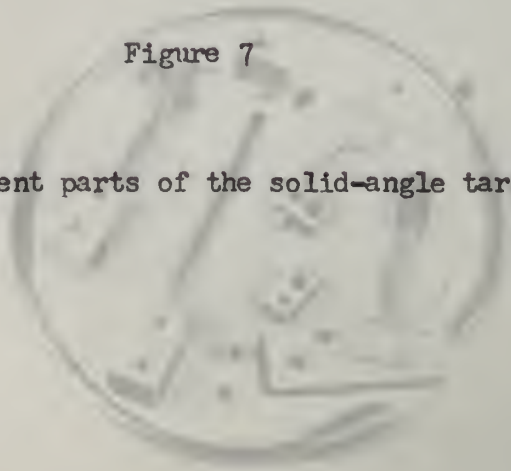
Oblique view of solid-angle target mount in place over the carbon rod assembly. Only one ring of the mount is shown to simplify the picture detail. It is evident that literally an umbrella of targets can be spread over the evaporative point. With isotropic evaporation, this spherical surface provides targets of homogeneous thickness.

Figure 6



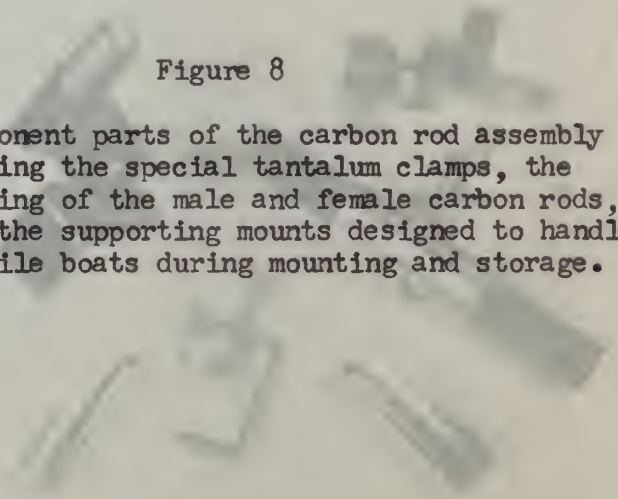
Looking down onto the evaporator table, one observes how the L-shaped aluminum shields lying on their tripod mount can be adjusted. This gives all targets exposure to the evaporative point while shielding them from the carbon clamps, etc., which heat during the evaporating cycle and might contribute contamination.

Figure 7



Component parts of the solid-angle target mount.

Figure 8



Component parts of the carbon rod assembly showing the special tantalum clamps, the shaping of the male and female carbon rods, and the supporting mounts designed to handle fragile boats during mounting and storage.

On the first attempts to evaporate the vanadium, we supported about eight target frames on horizontal rods clamped to the main vertical rods. A 1/2-inch carbon rod about 4" long was suspended between the wired rods by means of two tantalum "adapters" which held the carbon rod with good electrical contact. The adapters were held firm by stainless-steel clamps to the horizontal bronze rods. The carbon rod was "necked down" in the center and a hole was made in the top of this necked-down portion forming a "boat" in which to hold the vanadium pellets. The boat formed a high electrical resistance and, hence, concentrated the heat under the vanadium.

This method failed: If the heater current was brought up too quickly, the vanadium apparently vaporized locally and shot off "bullets" which broke the Formvar backings; if the heater current was brought up slowly enough, the vanadium melted uniformly, but it then made good electrical contact with the carbon. The resistance lowered at this point so that the heating was no longer localized at the vanadium.

Three steps were taken to improve the situation. First two brass rings were fashioned to be supported by the vertical rods and, in turn, support concentric rings of target frames (see Figures 5, 6, and 7). Care was taken during installation to center the assembly and to keep approximately equal radial distances from the evaporative

In the final attempts to prepare the machine, we mounted about eight target frames on horizontal rods placed to the main vertical rods. A 1/8-inch carbon rod about 6" long was suspended between the wired rods by means of two tentative "adjusters" which held the carbon rod with good electrical contact. The adjusters were held firm by rubber-band slings to the horizontal brass rods. The carbon rod was "vertical down" in the center and a hole was made in the top of this cylinder-brass portion leading a "wire" to which to hold the vacuum pulling. The base formed a high electrical resistance rod, hence, recommended the best results the machine.

This method failed. If the heater current was brought up too quickly, the machine apparently vaporized loosely and shot off "bullets" which broke the Pyrex insulators; if the heater current was brought up slowly enough, the machine melted uniformly, but it then made good electrical contact with the carbon. The metallizing layered at this point so that the coating was no longer insulated at the magnetics.

Three steps were taken to improve the situation. First the brass rings were insulated to be supported by the vertical rods and, in turn, accepted concentric rings of Pyrex frames (see Figure 5, 6, and 7). Care was taken during installation to weave the nichrome coil to keep approximately equal radial clearance from the microcoating

point. With this "solid angle" mount, we were able to form an umbrella of about twenty target frames and thereby increase our probability of realizing good targets on any single run; such an installation would also seem desirable for scarce or expensive materials. In addition, with such uniformity of intercepted solid angle, as well as nearly isotropic evaporation, we were able to produce nearly homogeneous groups of targets; this is a distinct advantage, since many targets are invariably needed to complete one's data. Another attractive feature of the mount is that the rings can be located at different radii, thus giving two distinct groups of targets (thick and thin) for a single run.

Second, an adjustable tripod stand (see Figure 12) with a hole in the center was made which sat over the heating elements, and on this were placed two L-shaped pieces of aluminum. Thus, we were able to form an aperture over the spot where the vanadium was vaporized and to adjust the size of the aperture as desired by sliding the L-shaped pieces. This shielded the Formvar backings from the heat of the steel clamps, tantalum adapters, and carbon rod. It also reduced the hazard of target impurities from these sources.

Third, the idea of a carbon boat was abandoned, and, instead, two carbon rods, each about 2 inches long were suspended horizontally so as to "pinch" a vanadium pellet between the ends (see Figures 9,

Figure 9

Installation of fragile carbon boats without breakage is difficult. Here is demonstrated the advantage of using a supporting mount. Using this mount, we completely eliminated breakages during installation and storage.

Figure 10

Close-up of a vanadium pellet pinched between the male and female carbon rod. After the pellet is fused to the female rod, the top cover of the carbon cavity is ground away to give better isotropic evaporation. The male rod is then ground to nearly a filament point and held in compression against the fused pellet by the tantalum spring clamp.

Figure 11

Carbon rod assembly in place on the evaporator table showing the pinching action provided by the tantalum spring clamps.

10, and 11). The adapters (Figures 9 and 11) were made so that they could exert longitudinal spring force on the carbon rods, as well as to tolerate torsion and expansion forces during the heating cycle.

In the end of one carbon rod, a small hole was ground to receive a vanadium pellet, and the other rod was sharpened for a point contact. It was found that the vanadium could then be fused to the female rod after which the top cover of the carbon cavity was ground away to afford better isotropic evaporation. The small rod was then ground to nearly a filament point, moved into contact position against the vanadium, and held under compression by the tantalum spring clamp.

Thus, the heat was concentrated on the vanadium, forming an "atomic spray gun" so to speak; the resistance did not change appreciably throughout the run, and it was possible to make very satisfactory targets with this arrangement.

After the vanadium was deposited, the targets were coated again with two double layers of Formvar. The resulting targets showed no sign of breakage under the beam after exposures of around 4000 microcoulombs.

10, and 11). The airplane (Figures 9 and 11) were made so that they could exert longitudinal spring force on the carbon rods, as well as to tolerate torsion and expansion forces during the heating cycle.

In the end of one carbon rod, a small hole was ground to receive a vanadium pellet, and the other rod was sharpened for a point contact. It was found that the vanadium could then be fused to the female rod after which the top cover of the carbon cavity was ground away to afford better isotropic evaporation. The small rod was then ground to nearly a filament point, moved into contact position against the vanadium, and held under compression by the tantalum spring clamp.

Thus, the heat was concentrated on the vanadium, forming an "atomic array gun" so to speak; the carbonrods did not change appreciably throughout the run, and it was possible to make very satisfactory targets with this arrangement.

After the vanadium was deposited, the targets were coated again with two double layers of Formvar. The resulting targets showed no sign of breaking under the beam after exposures of around 1000 microcoulombs.

## III. THEORY AND COMPUTATIONS

### Part A. (d,p) Theory

The (d,p) reaction was considered anomalous for some time in that wave mechanics, which explained barrier penetration nicely, was unable to account for the occurrence of (d,p) reactions at deuteron energies low with respect to barrier height.

The Oppenheimer-Phillips explanation which appeared in 1935 explained the penetration at low energies by assuming that the deuteron "stretches out" radially with the proton part repelled by the Coulomb field and the neutron part continuing unopposed by the field until the neutron is absorbed and the proton is repelled. Thus, this stripping is more of a neutron-capture process than a real (d,p) nuclear reaction.

However, at higher energies, there is a greater chance that the whole deuteron is captured by the nucleus. Then the nucleus can re-emit a proton in a true (d,p) nuclear reaction.

Thus, the term (d,p) reaction really includes two different processes. The stripping reaction tends to emit protons in the forward direction, whereas the nuclear reaction is isotropic. Our experiment does not differentiate between the two because our measurements are made at 90 degrees to the incident beam.

## III. THEORY AND CONSTRUCTION

### Part A. (d,p) Theory

The (d,p) reaction was considered amenable for some time in that very simplistic, which emphasizes heavier penetration cross-sections, would be accounted for the correspondence of (d,p) reactions as distinctive reactions low with respect to heavier target.

The Oppenheimer-Phillips mechanism which appeared in 1935 explained the disintegration of low energies by assuming that the deuteron fragments only partially with the proton part repelled by the Coulomb field and the neutron part continuing unopposed by the field until the neutron is absorbed and the proton is repelled. Thus, this disintegration is more of a quasi-elastic process than a real (d,p) nuclear reaction.

However, at higher energies, there is a greater chance that the whole deuteron is captured by the nucleus. Then the nucleus can re-emit a proton in a true (d,p) nuclear reaction.

Thus, the term (d,p) sometimes really includes two different phenomena. The stripping reaction tends to peak forward in the forward direction, whereas the nuclear reaction is isotropic. The experiment does not differentiate between the two because our measurements are made at 90 degrees to the incident beam.

Part B. Computations

Figure 13 shows the proton spectrum which resulted from the deuteron bombardment at 5.74 Mev. The plot was labeled by assigning letters alphabetically to each noticeable peak. If a peak seemed to have substructure, the subpeaks were numbered. Of these groups, only C seemed to be due to a known impurity. This seems to be the ground state of $C^{14}$ from the $C^{13}(d,p)C^{14}$ reaction. The survey was not continued to the point where the first $C^{12}(d,p)C^{13}$ peak should appear. All the groups were then examined, as described below. Another such plot was obtained for the proton peaks down through F2 at deuteron energy of 5.00 Mev. A third such plot was obtained for the rest of the energy spectrum using a deuteron energy of 6.48 Mev.

In analyzing these data, it was noticed that the structure of the peaks did not reproduce itself exactly from one energy to another. These small changes made it impossible for us to specify completely the multiplet structure at O and P, for instance. Also, some of the smaller groups, such as E, did not reproduce clearly as peaks.

Therefore, we set up the following standards to apply to a group before we called it a probable level in $V^{52}$:

1. The peaks should have a maximum count of about 20 or more at each of the two deuteron energies so as to be something appreciably different from random background fluctuation.

Part 1. Conclusions

Figure 12 shows the proton spectrum which resulted from the deuteron bombardment at 5.75 Mev. The plot was labeled by assigning levels arbitrarily to each particle peak. If a peak appeared in both substructures, the substructure was preferred. Of course, only C proved to be low in a known impurity. This seems to be the ground state of $C^{13}$ from the $C^{13}(d,p)C^{14}$ reaction. The surprise was not predicted in the point where the first $C^{12}(d,p)C^{13}$ peak should appear. All the groups were then examined, as described before. Another peak was obtained for the higher peak from theory through its deuteron energy of 5.00 Mev. A third peak was obtained for the peak of the energy spectrum using a deuteron energy of 5.19 Mev.

In analyzing these data, it was noticed that the structure of the peaks did not resemble itself exactly from one energy to another. These small changes made it impossible for us to specify completely the initial excitations at 0 and 5, for instance. Also, some of the smaller groups, such as 3, did not resemble closely as peaks.

Therefore, we set up the following standards to qualify the group before we called it a reasonable level in $C^{12}$.

1. The peaks should have a maximum width of about 30 or more at each of the two deuteron energies so as to be sufficiently appreciably different from random background fluctuation.

Hρ IN KILOGAUSS CENTIMETERS

2. The peaks should have a fairly clearly defined high-energy edge so that the 1/3 height could be well determined.

3. The Q-value should be determined to an agreement of 10 kilovolts or less from computations made from one or more exposures at each of at least two different energies. This requirement is apparent from the formula for Q-value:

$$Q = \frac{M_{res} + M_{out}}{M_{res}} E_o - \frac{M_{res} - M_{in}}{M_{res}} E_{in} \text{ (for } 90^\circ \text{ emergence).}$$

Here for a given peak, both $M_{res}$ and Q are unknown so an energy shift in $E_{in}$ is necessary to give two equations to determine the two unknowns.

This third restriction is rather conservative in view of the probable error; however, it happened that all peaks which met the first two requirements also met the third.

A sample Q-value calculation is shown here as follows:

2. The peaks should have a fairly sharply defined high-energy edge so that the $1/\beta$ weight would be well determined.

3. The $\eta$-value should be determined to an agreement of 10 kilovolts or less from computations made from one or more sequences at least of at least two different energies. This requirement is expressed from the formula for $\eta$-value:

$$\eta = \frac{E_{max} + E_{min}}{E_{max}} E_{\gamma} - \frac{E_{max} - E_{min}}{E_{max}} E_{in} \text{ (for 2nd energy).}$$

Here for a given peak, both $E_{max}$ and $\eta$ are unknown so an energy shift in $E_{in}$ is necessary to give two equations to determine the two unknowns.

This third restriction is rather conservative in view of the probable error; however, it happened that all peaks which met the first two requirements also met the third.

A sample $\eta$-value calculation is shown here as follows:

0 is from values of energy vs. $E_r$ .
Corr linear interpolation is adequate

$$Q = \frac{M_{res} + M_{out}}{M_{res}} E_o - \frac{M_{res} - M_{in}}{M_{res}} E_{in} .$$

where:

$M_{res} = V^{52} = 51.96165$ (calculated as shown)

$M_{in} = {}_1H^2 = 2.014735$ (Li et al)

$M_{out} = {}_1H^1 = 1.008142$ (Li et al)

The computation for the mass of $V^{52}$ is as follows:

$V^{51} + n = V^{52} + 7.305$ Mev (Bartholomew and Kinsey)

$d = n + p - 2.225$ (computed from data by Li et al)

$V^{52} = V^{51} + (d - p) - 5.080$ Mev

$= 50.96052^4 + 1.006593 - 0.00546$

$V^{52} = 51.96165$

Therefore:

$$Q = 1.01940\ E_o - 0.96123\ E_{in}$$

$$\eta = \frac{E_{ma} + E_{mb}}{E_{ma}} \eta_b - \frac{E_{ma} - E_{mb}}{E_{ma}} \eta_{ca} =$$

where:

$E_{ma} = \gamma_{Z^2} = 32.0515$ (calculated as above)

$E_{mb} = \gamma_{Z^1} = 5.0147\Delta$ (Ii et al)

$E_{mb} = \gamma_{E^2} = 1.0033\Delta$ (Ii et al)

The computation for the value of $\gamma_{Z^2}$ is as follows:

$\gamma_{Z^1} + n = \gamma_{Z^2} = 7.305$ mev (Swedlunds and Kinney)

$d = n + p - 2.625$ (computed from data by Ii et al)

$\gamma_{Z^2} = \gamma_{Z^1} + (d - p) - 2.050$ mev

$= 10.9605^{b} + 1.0033 - 0.0026$

$\gamma_{Z^2} = 32.0515$

Therefore:

$\eta = 1.0140\ \eta_b - 0.0033\ \eta_{ca}$

| | |
|---|---|
| | 10.59656 |
| | -5.52131 |
| Q = | 5.075 |
| Relativistic correction | .001 |
| $Q_{corr}$ = | 5.076 Mev |

The relativistic correction to the classical Q-value was determined according to the formula:

$$\Delta = (E_i)^2 \frac{M_{res}^2 - M_i^2}{1862\ M_{res}^3} + (E_o)^2 \frac{M_{res}^2 - M_o^2}{1862\ M_{res}^3} - \frac{M_i\ M_o}{931\ M_{res}^3} .$$

This positive correction was found to vary from about 0.8 kev for $E_d$ = 5.74 Mev and $E_p$ = 7 Mev to about 1.4 kev for $E_d$ = 6.48 and $E_p$ = 10 Mev, so that this correction was made by adding 1 kev to each classical Q-value obtained.

Part C. Survey of Impurities

In determining the Q-values, we obtained agreement to within 10 kev for the values obtained at the two different bombarding energies for each of the twenty proton groups. This agreement is better than could be expected considering the probable errors

| | |
|---|---|
| | 10.7805 |
| | -4.7131 |
| $\theta$ = | 5.075 |
| Ionization correction | .003 |
| $\theta_{corr}$ = | 5.078 kev |

The multiplicative correction to the observed $\theta$-value was determined according to the formula:

$$\Delta = (\Delta\eta)^2 \frac{\eta_{max}^2 - \eta_0^2}{2\eta_0 \eta_{max}^2} + (\Delta\eta_0)^2 \frac{\eta_{max}^2 - \eta_0^2}{2\eta_0 \eta_{max}^2} - \frac{\eta_0 \eta_0}{\eta_{max}^2} .$$

This positive correction was found to vary from about 0.3 kev for $\eta_0$ = 5.78 kev and $\eta_0$ = 7 kev to about 1.1 kev for $\eta_0$ = 6.46 and $\eta_0$ = 10 kev, so that this correction was made by adding 1 kev to each observed $\theta$-value obtained.

Part 5. Errors of Importance

In determining the $\theta$-values, we obtained agreement to within 10 kev for the values obtained at the two different bombarding energies for each of the energy groups. This agreement is better than could be expected considering the possible errors

assigned to the Q-values. However, if this $\Delta Q$ is assumed to be caused entirely by the wrong assignment of $M_{res}$ in the equation for Q-determination, we can combine Q-equations for two different values of $E_{in}$ to give:

$$\Delta Q = \left(\frac{M_{res} + M_o}{M_{res}}\right) \Delta E_o - \left(\frac{M_{res} - M_{in}}{M_{res}}\right) \Delta E_{in}$$

which, when solved for $M_{res}$, yields

$$M_{res} = \frac{M_o \, \Delta E_o + M_{in} \, \Delta E_{in}}{\Delta Q + (\Delta E_{in} - \Delta E_o)} .$$

Assuming $\Delta Q = \pm 10$ kev and the largest value of $\Delta E_o$, we obtain an uncertainty in $M_{res}$ of about 5 amu.

Of course, this means that mathematically the Q-values might have been caused by the (d,p) reaction with any nucleus of mass between 46 and 56.

The presence of any such impurity in an amount large enough to cause an appreciable proton yield does not seem possible, since the Formvar backings have been investigated extensively in the Laboratory and shown to contribute only C, O, and faint N groups. The chemical analysis of the vanadium used in the evaporation is given by the Vanadium Corporation of America as:

assigned to the $\beta$-values. However, if this $\alpha_1$ is assumed to be caused entirely by the wrong assignment of $\Delta\alpha_{in}$ in the equation for $\beta$-determination, we can consider $\beta$-equations for the different values of $\beta_{in}$ to give:

$$\Delta\beta = \left(\frac{M_{res} + M_{in}}{M_{res}}\right)\Delta\beta_o - \left(\frac{M_{res} - M_{in}}{M_{res}}\right)\Delta\beta_{in}$$

which, when solved for $M_{res}$, yields

$$M_{res} = \frac{M_o\,\Delta\beta_o + M_{in}\,\Delta\beta_{in}}{\Delta\beta + (\Delta\beta_{in} - \Delta\beta_o)} .$$

Assuming $\Delta\alpha = \pm 30$ kev and the largest value of $\Delta\beta_o$, we obtain an uncertainty in $M_{res}$ of about 5 kev.

Of course, this error does mathematically the $\beta$-values might have been caused by the $(d,p)$ reaction with any mixture of mass between 1d and 2d.

The presence of any such impurity in an amount large enough to cause an appreciable proton yield does not seem possible, since the Fermi analysis have been investigated extensively in the laboratory and shown to contribute only $d_o$, $p_o$, and fast $d$ groups. The standard analysis of the variation used in the evaporation is given by the Fermi Corporation of America as:

| Vanadium Metal | | (99.7 percent pure) |
|---|---|---|
| V | 96.6 - 99.8 | " |
| Si | .05 | " |
| Fe | .05 | " |
| Al | less than .05 | " |
| $N_2$ | less than .05 | " |
| $O_2$ | balance | |

Here we need also note that vanadium is practically mono-isotopic, consisting of

| | |
|---|---|
| $V^{51}$ | 99.76 percent |
| $V^{52}$ | .24 percent. |

As an additional check on the impurities, a proton elastic survey was made of the actual target used. The survey extended from a mass of $\infty$ down through the carbon group. The plot of the survey is shown in Figure 14. An analysis of the peaks is given below: (for $E_{in}$ = 6.52 Mev)

| Transition Metal | (99.7 percent pure) |
|---|---|
| $\gamma$ | 96.0 - 99.3 " |
| $\alpha_1$ | .08 " |
| $\gamma_n$ | .05 " |
| $\alpha_2$ | less than .02 " |
| $\sigma_f$ | less than .02 " |
| $\sigma_a$ | Indices |

Here we need also note that neutrino is spectrically indecipherable, resulting at

| | |
|---|---|
| $\gamma_{f1}$ | 99.78 percent |
| $\gamma_{f2}$ | .22 percent. |

In an additional study on the impurities, a prudent elastic survey was made of the actual target used. The survey indicated some a mere of $\sigma$ then through the carbon group. The plot of the survey is shown in figure 14. An analysis of the peaks is given below: (for $E_{in}$ = 6.52 Mev)

Figure 14

Hρ IN KILOGAUSS CENTIMETERS

| Designation | Maximum Proton Count | Apparent Source |
|---|---|---|
| 1 | 15 | Elastic scattering from M = 167 |
| 2 | 10 | Elastic scattering from M = 62 |
| 3 | 30 | Elastic scattering from M = 41 |
| 4 | 35 | Elastic scattering from M = 34 |
| 5 | 15 | Elastic scattering from M = 32 |
| 6 | 15 | Elastic scattering from M = 23 |
| 7 | 80 | $V^{51*}$ (0.32) level |
| 8 | 15 | $V^{51*}$ (0.48) level |
| 9 | 40 | Elastic scattering from M = 14. |
| $V^{51}$ | 1454 | |
| $O^{16}$ | Very large | |
| $C^{12}$ | Very large | |

Therefore, the elastic survey seems to show no trace of an impurity which could give rise to the peaks ascribed to $V^{52}$. However, it is fair to point out that the very impurities, which could theoretically cause the proton groups, are the ones which would be very difficult to detect in the large $V^{51}$ peak.

Moreover, on the basis of the vanadium analysis and a consideration of the evaporation system, it is improbable that the groups tabulated later could be caused by any other reaction than $V^{51}(d,p)V^{52}$.

| Location | Neutron Count | Apparent Source |
|---|---|---|
| 1 | 15 | Elastic scattering from N = 147 |
| 2 | 10 | Elastic scattering from N = 62 |
| 3 | 30 | Elastic scattering from N = 41 |
| 4 | 37 | Elastic scattering from N = 34 |
| 5 | 25 | Elastic scattering from N = 32 |
| 6 | 15 | Elastic scattering from N = 23 |
| 7 | 80 | $\gamma_{52}$ (0,32) level |
| 8 | 15 | $\gamma_{51}$ (0,40) level |
| 9 | 40 | Elastic scattering from N = 14 |
| $\gamma_{51}$ | 1450 | |
| $\gamma_{16}$ | Very large | |
| $\gamma_{12}$ | Very large | |

Therefore, the elastic survey seems to show no trace of an impurity which could give rise to the peak associated to $\gamma_{51}$. However, it is fair to point out that the very impurities, which could theoretically cause the proton groups, are the same which would be very difficult to detect in the large $\gamma_{51}$ peak.

Moreover, on the basis of the resulting analysis and a correlation of the irradiation system, it is improbable that the process radiolytical labor could be caused by any other reaction than $\gamma_{51}(d,n)\gamma_{52}$.

Part D. Probable Errors

The assignment of standard deviations or probable errors to the Q-values determined was not possible on a statistical basis, since the number of measurements was too small to permit a statistical treatment.

An uncertainty was arrived at by examining each step of the process by which a measurement is made in this Laboratory. These sources of possible error[11] were the value of Hr for polonium alpha-particles, angle of incident beam with median plane of annular magnet, deviation of observation angle from 90 degrees, surface contamination of target, plate position, position of leading edge of group, stability of annular magnetic field, stability of deflecting magnetic field. An uncertainty was assigned at each step, and these sources of errors were compounded to give an over-all uncertainty of the quantity measured.

Elkind[6] made an analysis of this sort for the measurement of output energy and concluded that the fractional uncertainty is about 5.6:10,000.

Turner[12] made a statistical analysis for the measurement of input energy and concluded that the uncertainty in the measurement of input energy is about 0.1 percent. Although if $E_{in}$ is measured from elastic scattering, the uncertainty should be the same as that for $E_{out}$.

Part D. Probable Errors

The assignment of standard deviations or probable errors to the Q-values determined was not possible on a statistical basis, since the number of measurements was too small to permit a statistical treatment.

An uncertainty was arrived at by examining each step of the process by which a measurement is made in this laboratory. These sources of possible error[11] were the value of $M$, for polonium alpha-particles, angle of incident beam with median plane of scattering magnet, deviation of observation angle from 90 degrees, surface contamination of target, plate position, position of leading edge of group, stability of magnetic magnetic field, stability of deflecting magnetic field. An uncertainty was assigned at each step, and these sources of errors were compounded to give an over-all uncertainty of the quantity measured.

Ritter[6] made an analysis of this sort for the measurement of output energy and concluded that the fractional uncertainty is about 5.5:10,000.

Tower[12] made a statistical analysis for the measurement of input energy and concluded that the uncertainty in the measurement of input energy is about 0.1 percent. Although if $E_{in}$ is measured from elastic scattering, the uncertainty should be the same as that for $E_{out}$.

However,

$$Q = \left(\frac{M_{res} + M_o}{M_{res}}\right)E_o - \left(\frac{M_{res} - M_{in}}{M_{res}}\right)E_{in}$$

so that the uncertainty in Q is the square root of the sum of the squares of two terms, each of which is the product of an energy, its fractional uncertainty, and its mass ratio factor (near unity for $V^{52}$.)

For each Q-value, the highest value of $E_o$ and $E_{in}$ was chosen to give conservative results. This assumes that the leading edges of all peaks were equally well defined. The uncertainties all lay between 7.5 and 8.5 kev.

The value of 8 kev seems conservative, as far as reproducibility of data is concerned, since all of our Q-values fell within 5 kev of the average value.

The uncertainty of the level values was the square root of the sum of the squares of the ground-state uncertainty and the peak Q-value uncertainty. However, a smaller uncertainty in level separation can be arrived at whenever peak separations can be measured on the same plate.

## IV. DISCUSSION

In quoting results of the energy-level study, it is of course interesting to take note of previous work on the same subject.

Very little work has been done on the level nature of $V^{52}$ as compared with the large amount of information available for light nuclei; however, the $V^{51}(d,p)V^{52}$ reaction has been done several times previously.

The reaction was first done by Jarkovec[7], who found levels at 2.17 and 3.70 Mev, using 3.3-mev deuterons from a cyclotron. Later work on $\gamma$-rays was done by Jenny[8], and energy levels were compiled by Ajzenberg[1]. These Ajzenberg's compilations of levels is the most nearly complete of these earlier (d,p) investigations, it is included for comparison. The agreement of our work with his is not too striking, but in view of the large uncertainties of his work, we have a quantitative agreement in most cases.

The most nearly complete work on level nature was the published due $V^{52}$ in back of Bartholomew and Kinsey[2], which above the results of their $V^{51}(n,\gamma)V^{52}$ investigations of these levels. However, the assignment of levels from capture-ray energies is rather time until confirmed by information, such as results from (d,p) work. These results are also tabulated for comparison.

Our levels confirm all of Bartholomew and Kinsey's levels within the uncertainties of the data. However, it is apparent that our values lie consistently lower than theirs.

Their work suggested that the 0.8 level was really two levels with a separation of 50 kev. There we have two well-separated groups at 0.780 and 0.834 Mev, a separation of 54 kev. Also, their gamma-ray peaks, F, J, and L, suggested possible levels which seem to correspond respectively with our 1.402, 2.307, and 2.848 levels. No peak was observed to correspond to their gamma-ray peak D.

The following table summarizes our results, along with those of Bartholomew and Kinsey, and those of Abramov:

Our levels confirm all of Bertholdsen and Stoney's levels within the uncertainties of the data. However, it is apparent that our values lie consistently lower than theirs.

Their work suggested that the 0.8 level was really two levels with a separation of 50 kev. There we have two well-separated groups at 0.770 and 0.738 kev, a separation of 32 kev. Also, their gamma-ray peaks, $\gamma_1$, $\gamma_2$, and $\gamma_3$ suggested possible levels which seem to correspond respectively with our 1.168, 1.137, and 1.083 levels. No peak was observed to correspond to their gamma-ray peak $\gamma_4$.

The following table summarizes our results, along with those of Bertholdsen and Stoney, and those of Alvarez:

TABLE I
